

## The Relationships Among Working Memory, Math Anxiety, and Performance

Mark H. Ashcraft and Elizabeth P. Kirk  
Cleveland State University

Individuals with high math anxiety demonstrated smaller working memory spans, especially when presented with a computation-based span task. This reduced working memory capacity had no pronounced impact on fraction-like arithmetic when mental addition was performed concurrently with a memory load task. The effects of the reduction are generalized to a working memory–arithmetic transformation task. Overall, the results demonstrated that an individual's level of math anxiety, math anxiety, affects on-line performance in math related tasks and that this fear is a memory disruptor of working memory. The authors consider a possible mechanism underlying this effect—competition of central executive processes—and suggest that individual differences variables like math anxiety deserve greater empirical attention, especially on assessments of working memory capacity and functioning.

AFFECT IS A LEAD INVESTIGATOR'S aspect of human psychology, yet it is probably the aspect that often receives least regard in deserving math investigation. (Mandler, 1989, p. 1)

In this article, we examine a program of research that examines the possible cognitive consequences and correlates of mathematics anxiety. As discussed elsewhere (Ashcraft & Faust, 1994; Ashcraft, Kirk, & Hopkins, 1998), this work attempts to integrate two major independent lines of research that have coexisted since the early 1970s. The first concerns studies of math anxiety per se, beginning with the important article by Richardson and Suinn (1972) and largely conducted within the psychometric tradition. The second is the study of mathematical cognition itself, focusing on the underlying mental representations and procedures used in arithmetic and mathematics performance, while separating principally from Gross and Parkman's (1972) classic article.

It is surprising yet apparently true that up until that integrative research was begun, no one had considered whether math anxiety had any real effect on an individual's math performance. That is, an effect on underlying cognitive processes at the individual performs a math task. To be sure, the literature contains many reports of the general negative effects that math anxiety has on math performance and achievement (see the thorough meta-analysis by Hembree, 1990). For example, individuals with high math anxiety take fewer math courses, earn lower grades in the classes they do take, and demonstrate lower math achievement and

aptitude than their counterparts with low math anxiety. However useful this information is, it does not address the underlying cognitive processes involved in doing math, for example, mental processes that access the auditory representation of mathematical knowledge. The state is largely low of the work reported in McLeod and Artelt (1985), its focus is relatively slow problem-solving tasks, especially when evaluated in classroom settings, provides a fine-grained examination of sound representation and processes. Thus, the general focus of our research is to examine performance in worked cognitive frameworks and online tasks. We hope to examine the influence that math anxiety exerts on mathematical cognition and to identify the processing components that are so influenced.

### Math Anxiety and Performance

Across several initial studies, we have found substantial evidence for performance differences as a function of math anxiety. These differences typically are not observed on the basic whole-number facts of simple addition or multiplication (e.g.,  $2 + 9$ ,  $6 \times 8$ ) but are prominent when somewhat more difficult addition problems are tested. In particular, Ashcraft and Faust (1991; also Faust, Ashcraft, & Flock, 1996) have shown that high-math-anxiety participants have particular difficulty on two-column addition problems (e.g.,  $37 + 18$ ), owing largely to the carry operation. When such problems were answered correctly, the time estimate for the embodied carry operation was nearly three times as long for high-anxiety participants as it was for low-anxiety participants (Faust et al., 1996). Thus, high-math-anxiety participants showed slower, more effortful processing on a procedural aspect of performance, performing the carry operation (for suggestive evidence on math anxiety and procedural performance, it's numerical estimation task, see LeFevre, Goulet, & Wilson, 1993). Furthermore, their higher error rates on these problems, often showing classic speed-accuracy tradeoffs when confronted with relatively difficult arithmetic, indicated a willingness to sacrifice accuracy on especially difficult trials, either to avoid having to deal with the stimulus problem or merely to speed the experimental session along.
